MINIMAL SURFACE SINGULARITIES ARE LIPSCHITZ NORMALLY EMBEDDED

WALTER D NEUMANN, HELGE MØLLER PEDERSEN, AND ANNE PICHON

Abstract. Any germ of a complex analytic space is equipped with two natural metrics: the outer metric induced by the hermitian metric of the ambient space and the inner metric, which is the associated riemannian metric on the germ. These two metrics are in general nonequivalent up to bilipschitz homeomorphism. We show that minimal surface singularities are Lipschitz normally embedded, i.e., their outer and inner metrics are bilipschitz equivalent, and that they are the only rational surface singularities with this property. The proof is based on a preliminary result which gives a general characterization of Lipschitz normally embedded normal surface singularities.

1. Introduction

If \((X, 0)\) is a germ of an analytic space of pure dimension \(\dim(X, 0)\), we denote by \(m(X, 0)\) its multiplicity and by \(edim(X, 0)\) its embedding dimension.

Minimal singularities were introduced by J. Kollár in [12] as the germs of analytic spaces \((X, 0)\) of pure dimension which are reduced, Cohen-Macaulay, whose tangent cone is reduced and whose multiplicity is minimal in the sense that Abhyankar’s inequality

\[ m(X, 0) \geq edim(X, 0) - \dim(X, 0) + 1 \]

is an equality (see [12, Section 3.4] or [4, Section 5]).

In this paper, we only deal with normal surfaces. In this case, minimality can be defined as follows ([12, Remark 3.4.10]): a normal surface singularity \((X, 0)\) is minimal if it is rational with a reduced minimal (also called fundamental) cycle.

Minimal surface singularities play a key role in resolution theory of normal complex surfaces since they appear as central objects in the two main resolution algorithms: the resolution obtained as a finite sequence of normalized Nash transformations ([22]), and the one obtained by a sequence of normalized blow-up of points ([25]). The question of the existence of a duality between these two algorithms, asserted by D. T. Lê in [14, Section 4.3] (see also [4, Section 8]) remains open, and the fact that minimal singularities seem to be the common denominator between them suggests the need of a better understanding of this class of surface germs.

In this paper, we study minimal surface singularities from the point of view of their Lipschitz geometries, and we show that they are characterized by a remarkable metric property: they are Lipschitz normally embedded. Let us explain what this means.

1991 Mathematics Subject Classification. 14B05, 32S25, 32S05, 57M99.
Key words and phrases. bilipschitz, Lipschitz geometry, minimal surface singularity, Lipschitz normal embeddings.
If $(X, 0)$ is a germ of a complex variety, then any embedding $\phi: (X, 0) \hookrightarrow (\mathbb{C}^n, 0)$ determines two metrics on $(X, 0)$: the outer metric
\[ d_{out}(x_1, x_2) := ||\phi(x_1) - \phi(x_2)|| \quad \text{(i.e., distance in } \mathbb{C}^n) \]
and the inner metric
\[ d_{inn}(x_1, x_2) := \inf\{\text{length}(\phi \circ \gamma) : \gamma \text{ is a rectifyable path in } X \text{ from } x_1 \text{ to } x_2\}, \]
using the riemannian metric on $X \setminus \{0\}$ induced by the hermitian metric on $\mathbb{C}^n$. For all $x, y \in X$, $d_{inn}(x, y) \geq d_{out}(x, y)$, and the outer metric determines the inner metric. Up to bilipschitz equivalence both these metrics are independent of the choice of complex embedding. We speak of the (inner or outer) Lipschitz geometry of $(X, 0)$ when considering these metrics up to bilipschitz equivalence.

**Definition 1.1.** A germ of a complex normal variety $(X, 0)$ is Lipschitz normally embedded if inner and outer metrics coincide up to bilipschitz equivalence, i.e., there exists a neighbourhood $U$ of 0 in $X$ and a constant $K \geq 1$ such that for all $x, y \in U$
\[ \frac{1}{K} d_{inn}(x, y) \leq d_{out}(x, y). \]

It is a classical fact that the topology of a germ of a complex variety $(X, 0) \subset (\mathbb{C}^n, 0)$ is locally homeomorphic to the cone over its link $X^{\epsilon} = S^{2n-1}_{\epsilon} \cap X$, where $S^{2n-1}_{\epsilon}$ denotes the sphere with small radius $\epsilon$ centered at the origin in $\mathbb{C}^n$. If $(X, 0)$ is a curve germ then it is in fact bilipschitz equivalent to the metric cone over its link with respect to the inner metric, while the data of its Lipschitz outer geometry is equivalent to that of the embedded topology of a generic plane projection (see [21, 9, 19]). Therefore, an irreducible complex curve is Lipschitz normally embedded if and only if it is smooth. Our main result shows that this is not true in higher dimension: any minimal surface singularity is Lipschitz normally embedded. In section 8 we also prove a converse to this among rational singularities, so:

**Theorem 1.2.** A rational surface singularity is Lipschitz normally embedded if and only if is minimal.

The paper is organized as follows. In Section 2 we give basic definitions about generic projections of a normal surface germ and their polar curves and discriminants. In Section 3 we recall the geometric decomposition with rates of a normal surface germ given in [20], which completely describes the inner Lipschitz geometry and an important part of the outer geometry. The proof of theorem 1.2 is based on two preliminary results. The first one is a characterization of Lipschitz normally embedded surface singularities (Theorem 4.5). The second one is a complete description of the geometric decomposition of a minimal singularity given in Section 5 by using results of [6] and the explicit description of the polar and discriminant curves of minimal surface singularities given in [22] and [23]. Finally, one direction of Theorem 1.2 (minimal singularities are normally embedded) is proved in Section 6 and illustrated through an example in Section 7, and the other direction is proved in Section 8.

2. Generic projections

We denote by $G(k, n)$ the grassmannian of $k$-dimensional subspaces of $\mathbb{C}^n$. For $D \in G(n-2, n)$ let $\ell_D: \mathbb{C}^n \to \mathbb{C}^2$ be the linear projection with kernel $D$.

**Definition 2.1.** Let $(\gamma, 0) \subset (\mathbb{C}^n, 0)$ be a complex curve germ. Let $V \subset G(n-2, n)$ be the open dense subset such that for each $D \in V$, $D$ does not contain any limit of bisecant lines to $\gamma$. The projection $\ell_D$ is generic for $(\gamma, 0)$ if $D \in V$. (See [7] for the definition of the cone of limits of bisecants.)

**Definition 2.2.** ([16], (2.2.2)) and [23], V. (1.2.2). Let $(\mathbb{C}^n, 0)$ be the open dense subset such that for each $D$ of bisecant lines to $\gamma$ of surface germ. We assume that the restriction $\ell_D$ for $D$ is generic for $(\gamma, 0)$ if $D \in V$. (See [7] for the definition of the cone of limits of bisecants.)

**Remark 2.3.** ([16], (2.2.2)) and [23], V. (1.2.2). Let $(X, 0) \subset (\mathbb{C}^n, 0)$ be a normal surface germ. We assume that the restriction $\ell_D$ for $D$ is generic for its polar curve $\Pi_D$; $\Pi_D \subset X$ be the polar curve of this projection, i.e., the closure in $(X, 0)$ of the singular locus of the restriction of $\ell_D$ to $X \setminus \{0\}$, and let $\Delta_D = \ell_D(\Pi_D)$ be the discriminant curve.

There exists an open dense subset $\Theta \subset G(n-2, n)$ such that

1. for each $D \in \Theta$, the projection $\ell_D$ is generic for its polar curve $\Pi_D$;
2. $\{\Pi_D, 0) : D \in \Theta\}$ forms an equisingular family of curve germs in terms of strong simultaneous resolution.

We say the projection $\ell_D: \mathbb{C}^n \to \mathbb{C}^2$ is generic for $(X, 0)$ if $D \in \Theta$.

**Remark 2.4.** ([16], (2.2.2)) and [23], V. (1.2.2). Let $(X, 0) \subset (\mathbb{C}^n, 0)$ be a normal surface germ. We assume that the restriction $\ell_D$ for $D$ is generic for its polar curve $\Pi_D$; $\Pi_D \subset X$ be the polar curve of this projection, i.e., the closure in $(X, 0)$ of the singular locus of the restriction of $\ell_D$ to $X \setminus \{0\}$, and let $\Delta_D = \ell_D(\Pi_D)$ be the discriminant curve.

There exists an open dense subset $\Theta \subset G(n-2, n)$ such that

1. for each $D \in \Theta$, the projection $\ell_D$ is generic for its polar curve $\Pi_D$;
2. $\{\Pi_D, 0) : D \in \Theta\}$ forms an equisingular family of curve germs in terms of strong simultaneous resolution.

We say the projection $\ell_D: \mathbb{C}^n \to \mathbb{C}^2$ is generic for $(X, 0)$ if $D \in \Theta$.

3. Lipschitz geometry and geometric decomposition of a normal surface singularity

In this section, we describe the geometric decomposition of $(X, 0)$ introduced in [20], which completely determines the inner geometry and is an invariant of the outer geometry. We give first the description through resolution as presented in [20] Section 9] and we give an alternative but equivalent description through carrousel decomposition at the end of the section. See also [20] for more details.

We need to define the contact exponent between two germs of curves. Let $(C, 0)$ and $(D, 0)$ be two irreducible plane curve germs intersecting only at 0. Let us choose coordinates $x$ and $y$ in $\mathbb{C}^2$ so that $C$ and $D$ admit Puiseux parametrizations respectively

$$y = \alpha(x^{1/m}) = \sum_{i \geq m} a_i x^{i/m} \quad \text{and} \quad y = \beta(x^{1/n}) = \sum_{j \geq n} b_j x^{j/n},$$

where $m$ and $n$ are the multiplicities of $C$ and $D$.

Replacing $x$ by $\omega x$ in $\alpha$ (resp. $\beta$) where $\omega^m = 1$ (resp. $\omega^n = 1$), we get all the Puiseux parametrizations of $C$ (resp. $D$).

Denote by $\{\alpha_i(x^{1/m})\}_{i=1}^m$ the set of Puiseux parametrizations of $C$ and $\{\beta_j(x^{1/n})\}_{j=1}^n$ that of $D$.

**Definition 3.1.** The contact exponent between $C$ and $D$ is the rational number defined by:

$$\rho_{C,D} = \max_{1 \leq i \leq m, 1 \leq j \leq n} \{\text{ord}_x(\alpha_i(x^{1/m}) - \beta_j(x^{1/n}))\}$$
More generally, if $C, D$ are two germs of curves in $(\mathbb{C}^n, 0)$ intersecting only at 0, we define the contact exponent $q_{C,D}$ between $C$ and $D$ as the contact exponent between $\ell(C)$ and $\ell(D)$ where $\ell : \mathbb{C}^n \to \mathbb{C}^2$ is a generic projection for $C \cup D$.

Notice that $q_{C,D}$ depends neither on the choice of $\ell$ nor on that of the coordinates $x$ and $y$. Notice also that the contact exponent between two smooth curves is an integer. It is in fact the minimal number of blow-ups of points necessary to separate their strict transforms.

In order to define the geometric decomposition of $(X, 0)$, we consider the minimal good resolution $\pi_0 : (\bar{X}_0, E) \to (X, 0)$ with the following two properties:

1. it resolves the basepoints of a general linear system of hyperplane sections of $(X, 0)$ (i.e., it factors through the normalized blow-up of the maximal ideal of $X$);
2. it resolves the basepoints of the family of polar curves of generic plane projections (i.e., it factors through the Nash modification of $X$).

This resolution is obtained from the minimal good resolution of $(X, 0)$ by blowing up further until the basepoints of the two kinds are resolved. We denote by $\Gamma_0$ the dual resolution graph of $\pi_0$.

**Definition 3.2.** An $L$-curve is an exceptional curve in $\pi_0^{-1}(0)$ which intersects the strict transform of a generic hyperplane section. The vertex of $\Gamma_0$ representing an $L$-curve is an $L$-node.

A $P$-curve ($P$ for “polar”) will be an exceptional curve in $\pi_0^{-1}(0)$ which intersects the strict transform of the polar curve of any generic linear projection. The vertex of $\Gamma_0$ representing this curve is a $P$-node.

A vertex of $\Gamma_0$ is called a node if it is an $L$- or $P$-node or has valency $\geq 3$ or represents an exceptional curve of genus $> 0$.

A string of a resolution graph is a connected subgraph whose vertices have valency 2 and are not nodes, and a bamboo is a non-node vertex of valency 1 union a string attached to it.

Now, consider the resolution $\pi : \bar{X} \to X$ obtained from $\bar{X}_0$ by blowing up each intersection point of pairs of curves of $\pi^{-1}(0)$ which correspond to nodes of $\Gamma_0$. We then obtain a resolution satisfying (1) and (2) and such that there are no adjacent nodes in its resolution graph. Let $\Gamma$ be the resolution graph of $\pi$. Denote by $E_1, \ldots, E_r$ the exceptional curves in $E = \pi^{-1}(0)$ and by $v_k$ the vertex of $\Gamma$ corresponding to $E_k$.

For each $k = 1, \ldots, r$, let $N(E_k)$ be a small closed tubular neighbourhood of $E_k$ and let

$$N'(E_k) = N(E_k) \setminus \bigcup_{k' \neq k} N(E_{k'}).$$

For any subgraph $\Gamma'$ of $\Gamma$ define:

$$N(\Gamma') := \bigcup_{v_k \in \Gamma'} N(E_k) \quad \text{and} \quad N'(\Gamma') := N(\Gamma) \setminus \bigcup_{v_k \notin \Gamma'} N(E_k).$$

We now describe the geometric decomposition of $(X, 0)$. It is a decomposition of $(X, 0)$ as a union of semi-algebraic pieces of three types: $B(1), B(q)$ with $q > 1$ and $A(q, q')$ where the $q < q'$ are rational numbers $\geq 1$. The pieces $B(1)$ are metrically conical, i.e., bilipschitz equivalent to a strict metric cone in the inner metric. For each piece $B(q)$ with $q > 1$, $B(q) \setminus \{0\}$ fibers over a punctured disk $D^2 \setminus \{0\}$ with
2-manifold fibers having diameter of order $O(t^q)$ at distance $t$ from the origin. We call $q$ the rate of $B(q)$. Each $A(q, q')$ is an intermediate piece between a $B(q)$ and a $B(q')$ piece and is topologically the cone on a toral annulus $T^2 \times I$. For a more precise definition of pieces see [20 Section 2].

If $v_j$ is a vertex of $\Gamma$, we denote by $\Gamma_j$ the subgraph of $\Gamma$ consisting of $v_j$ union any attached bamboos.

**Proposition 3.3.** [20 Proposition 9.3] The pieces of the geometric decomposition of $(X, 0)$ are as follows:

1. the $B(1)$-pieces are the sets $\pi_1(N(\Gamma_j))$ where $v_j$ is an $L$-node;
2. each $B(q)$-piece for $q > 1$ is a set $\pi_1(N(\Gamma_j))$ where $v_j$ is a node which is not an $L$-node;
3. the $A(q, q')$-pieces (which have $1 \leq q < q'$) are the $\pi_1(N(\sigma))$ where $\sigma$ is a maximal string between two nodes.

In both cases (1) and (2), the rate $q$ is the contact exponent between the $\pi_1$-images of two curvettes of $E_j$ meeting $E_j$ at distinct points.

If $E'$ is an irreducible component of a normal crossing divisor $E$ in a complex smooth surface $S$, we call curvette of $E'$ a small smooth curve on $S$ transversal to $E'$ at a smooth point of $E$.

**Remark 3.4.** The geometric decomposition of $(X, 0)$ is a refinement of the thick-thin decomposition of $(X, 0)$ introduced in [6]. Namely the thick part of $(X, 0)$ is the union of $B(1)$ pieces plus adjacent $A(1, q)$-pieces.

The geometric decomposition can be encoded in the dual resolution graph $\Gamma$ of $\pi$ decorated with a rate $q$ at each node. See the left graph in Example 5.7.

In [20 Definition 8.6], we define an equivalence relation between pieces by saying that two pieces with same rate $q$ are equivalent, if they can be made equal by attaching a “$q$-collar” (a $B(q)$ piece which is topologically the cone on $T^2 \times I$) at each boundary component. Similarly, two $A(q, q')$-pieces are equivalent if they can be made equal by removing a $q$-collars at the outer boundaries and removing $q'$-collars at the inner boundaries.

**Proposition 3.5.** [20 Proposition 8.7] The geometric decomposition is unique up to equivalence of the pieces and it is an invariant of the outer Lipschitz geometry.

Let us now explain how the geometric decomposition is related (and even built) from the geometry of the discriminant of a generic plane projection.

We first construct a decomposition of the germ $(C^2, 0)$ into $B(q)$- and $A(q, q')$-pieces based on a resolution of $\Delta$.

Let $\rho: Y \to C^2$ be the minimal sequence of blow-ups starting with the blow-up of $0 \in C^2$ which resolves the basepoints of the family of images $\ell(P\Pi_D)$ by $\ell$ of the polar curves of generic plane projections and let $\Delta$ be some $\ell(P\Pi_D)$. We set $\rho^{-1}(0) = \bigcup_{k=1}^m C_k$, where $C_1$ is the exceptional curve of the first blow-up.

Denote by $R$ the dual graph of $\rho$, so $v_1$ is its root vertex. We call a $\Delta$-curve an exceptional curve in $\rho^{-1}(0)$ intersecting the strict transform of $\Delta$, and a $\Delta$-node a vertex of $R$ which represents a $\Delta$-curve. We call any vertex of $R$ which is either $v_1$ or a $\Delta$-node or a vertex with valency $\geq 3$ a node of $R$. A string is, as in Definition 3.2, a connected subgraph whose vertices have valency 2 and are not nodes, and a bamboo is again a non-node vertex of valency 1 union a string attached to it.
If two nodes are adjacent, we blow up the intersection points of the two corresponding curves in order to create a string between them. Denote $\rho': Y' \to C^2$ the obtained resolution.

The decomposition of $(C^2, 0)$ is as follows:

1. the single $B(1)$-piece is the set $\rho'(N(C_1))$;
2. the $B(q)$-pieces for $q > 1$ are the sets $\rho'(N(R_k))$ where $R_k$ is a subgraph of $R$ consisting of a node $v_k$ which is not the root $v_1$ plus any attached bamboo. The rate $q$ is the contact exponent between the $\rho'$-images of two curvettes of the exceptional curve corresponding to $v_k$;
3. the $A(q, q')$-pieces are the sets $\rho'(N(\sigma))$ where $\sigma$ is a maximal string between two nodes.

Definition 3.6. We call this decomposition of $(C^2, 0)$ into $B$- and $A$-pieces the carrousel decomposition of $(C^2, 0)$ with respect to $\Delta$.

The pieces of the carrousel decomposition can also described in terms of truncated Puiseux parametrizations of the components of $\Delta$. See [6, Section 12] or [20, Sections 3, 7] for details.

Let us now describe how the carrousel decomposition of $(C^2, 0)$ with respect to $\Delta$ and the geometric decomposition of $(X, 0)$ are related.

Definition 3.7. Let $\ell: (X, 0) \to (C^2, 0)$ be a generic plane projection of $(X, 0)$ as defined in Section 2. Let $\Pi$ be its polar curve and $\Pi^*$ its strict transform in the resolution $\pi: \tilde{X} \to X$. A polar wedge about $\Pi$ is a neighborhood of $\Pi$ saturated by the $\pi$-images of neighbouring curvettes of $\Pi^*$. A $\Delta$-wedge is the $\ell$-image of a polar wedge. (For details see [6]).

According to [6, Proposition 3.4], $\ell$ is a Lipschitz map for the inner metric outside a polar wedge $A$ about $\Pi$. Moreover, $A$ and the $\Delta$-wedge $\ell(A)$ are union of $B$-pieces with trivial topology, i.e., the fibers are 2-disks (we call $D$-pieces such trivial $B$-pieces). More precisely, if $A_0 \subset A$ is a $D(s)$-piece, then $\ell(A_0)$ is also a $D(s)$-piece (with same rate $s$).

As a consequence of this, each piece of the carrousel decomposition of $(C^2, 0)$ just constructed lifts to a union of $A$ and $B$-pieces of the same type in $(X, 0)$. After absorption of the polar-wedges and of the $D(q)$-pieces which do not contain components of the polar curve (see [6, section 13]), one obtains the geometric decomposition of $(X, 0)$ previously described. In the case of minimal singularities, no absorption will be needed so we omit the details of absorption here.

This correspondence between the geometric decomposition of $(X, 0)$ and the carrousel decomposition of $(C^2, 0)$ can be read through the correspondence between the resolutions $\rho'$ and $\pi$ given by the Hirzebruch-Jung resolution process. This will be a key argument in the proof of Theorem 1.2 in Section 6. A full example is given in Example 5.7.

4. Characterization of Lipschitz normally embedded surface singularities

Definition 4.1. Let $\delta$ be a singular plane curve. We say rate of $\delta$ for any rational number which is either a characteristic Puiseux exponent of a branch of $\delta$ or the contact exponent between two branches of $\delta$. If $\delta$ is smooth its set of rates is empty.

The following easy remark will be useful in the induction of Section 6.
**Remark 4.2.** Let $e$ be the blow-up of the origin of $\mathbb{C}^2$ and let $(\delta,0) \subset (\mathbb{C}^2,0)$ be a singular plane curve germ. If $\delta$ is irreducible and its set of rates $A$ consists of numbers $\geq 2$, then the set of rates of $(\delta^*,\rho)$ is $A - 1$, where $\delta^*$ denotes strict transform by $e$. If $\delta_1$ and $\delta_2$ are two components of $\Delta$ whose strict transforms by $e$ meet $e^{-1}(0)$ at a single point $p$, and if $q$ is the contact exponent between $\delta_1$ and $\delta_2$, then the contact exponent between $\delta_1^*$ and $\delta_2^*$ equals $q - 1$.

Let $(X,0)$ be the germ of a normal complex surface and let $\ell: X \to \mathbb{C}^2$ be a generic plane projection. Let $\Pi$ be the polar curve of $\rho$ and let $\Delta = \ell(\Pi)$ be its discriminant curve. Let $\rho: Y \to \mathbb{C}^2$ be the resolution of $\Delta$ introduced in Section 3 and let $R$ be the dual graph of $\rho$.

**Definition 4.3.** A test curve is an irreducible curve $(\gamma,0) \subset (\mathbb{C}^2,0)$ which is the projection by $\rho$ of a curvette $\gamma^*$ of an exceptional curve in $\rho^{-1}(0)$ represented by a node of $R$ such that $\gamma^*$ and the strict transforms of $(\Delta,0)$ by $\rho$ do not intersect.

**Definition 4.4.** Let $(\gamma,0) \subset (\mathbb{C}^2,0)$ be a test curve. Let $C$ be the component of $\rho^{-1}(0)$ which intersects the strict transform $\gamma^*$. We define the inner rate $q_\gamma$ of $\gamma$ as the contact exponent between the $\rho$-images of two generic curvettes of $C$.

Let $\tilde{\rho}: (\mathbb{C}^n,0) \to (\mathbb{C}^2,0)$ be a plane projection which is generic for the curve $\ell^{-1}(\gamma)$. We define the outer rates of $\gamma$ as the rates of the plane curve $\tilde{\rho}(\ell^{-1}(\gamma))$. Notice that the outer rates of $\gamma$ do not depend on the choice of $\tilde{\rho}$.

**Theorem 4.5.** $(X,0)$ is Lipschitz normally embedded if and only if for any test curve $(\gamma,0)$, the outer rates of $(\gamma,0)$ satisfy the following conditions:

1. Any outer rate of $\gamma$ which is a characteristic exponent equals $q_\gamma$.
2. For any pair $\delta_1,\delta_2$ of components of $\ell^{-1}(\gamma)$, let $\pi: X' \to X$ be $\pi$ composed with a sequence of successive blow-ups of points which resolves the curve $\delta_1 \cup \delta_2$. Let $E_1$ and $E_2$ be the components of $\pi^{-1}(0)$ which intersect the strict transforms of $\delta_1$ and $\delta_2$, and let $q_0$ be the maximum among minimum of inner rates of vertices along paths joining the vertices $v_1$ and $v_2$ in the resolution graph of $\pi$. Then the contact exponent between the generic projections $\tilde{\rho}(\delta_1)$ and $\tilde{\rho}(\delta_2)$ equals $q_0$.

**Remark 4.6.** In fact, an outer rate of $\gamma$ which is a characteristic exponent is always $\geq q_\gamma$. Indeed, let $C_\nu$ be the exceptional curve of $\rho^{-1}(0)$ such that $\gamma^*$ is a curvette of $C_\nu$. Then $\Delta = \rho(N(C_\nu))$ is a $B(q_\gamma)$-piece in the sense of [20] Section 2 (see also [6] Section 11). Let $\tilde{\rho}: (X,0) \to (\mathbb{C}^2,0)$ be another generic projection. Note that $\tilde{\rho}(\ell^{-1}(B))$ is also a $B(q_\gamma)$-piece, so any characteristic exponent of a complex curve inside it is $\geq q_\gamma$.

Similar arguments show that the contact exponent between $\tilde{\rho}(\delta_1)$ and $\tilde{\rho}(\delta_2)$, as in Condition (2), is always $\geq q_0$.

**Remark 4.7.** Notice that Condition (2) for $\gamma$ does not depend on the choice of the resolution $\pi'$. In fact, one could take for $\pi'$ the resolution $\pi_\rho: \tilde{X} \to X$ of $(X,0)$ obtained by taking the pull-back of $\rho$ by $\ell$, then normalizing and then resolving the remaining quasi-ordinary singularities. It is easy to prove that $\pi_\rho$ is a good resolution for the lifting by $\ell$ of any test curve of $\rho$.

**Proof of Theorem** The proof will use some arguments already presented in [20], in particular in the proof of [20, 20.1].
Assume that there exists a test curve \((\gamma, 0) \subset (C^2, 0)\) which does not satisfy Condition \((\ast 1)\). Let \(\delta\) be a component of the lifting \(\ell^{-1}(\gamma)\) such that \(\ell(\delta)\) admits a characteristic exponent \(q > q_\gamma\).

Let \((x(w), y(w)) = (w^n, \sum_{i \geq n} b_i w^i)\) be a parametrization of \(\gamma\). Fix \(w_0 \in \mathbb{C}^\ast\) and consider the algebraic arc \(p: [0, 1] \to \gamma\) defined by \(p(t) = (x(tw_0), y(tw_0))\). Then \(p\) lifts to two semi-algebraic arcs \(\gamma_1, \gamma_2: [0, 1] \to \delta\) such that for all \(t\), \(\ell(\gamma_1(t)) = \ell(\gamma_2(t)) = p(t)\) and \(d_{out}(\gamma_1(t), \gamma_2(t)) = O(t^{q_\gamma})\).

Since \(\gamma_1(t)\) and \(\gamma_2(t)\) belong to different sheets of the cover \(\ell\), then for any path \(\sigma\) between them, the loop \(\ell(\sigma)\) will have to travel through the \(B(q_\gamma)\)-piece containing the point \(p(t)\), so \(\text{length}(\ell(\sigma)) \geq O(t^{q_\gamma})\). Since \(\ell\) is Lipschitz for the inner metric (outside polar-wedges which can be avoided by multiplying the length of \(\ell(\sigma)\) by a factor of \(\pi\)), we also have that the length of \(\sigma\) is \(\geq O(t^{q_\gamma})\). Therefore, we get \(d_{inn}(\gamma_1(t), \gamma_2(t)) \geq O(t^{q_\gamma})\). So

\[
\lim_{t \to 0} \frac{d_{out}(\gamma_1(t), \gamma_2(t))}{d_{inn}(\gamma_1(t), \gamma_2(t))} = 0,
\]

which implies that \((X, 0)\) is not Lipschitz normally embedded.

Assume now that \((\gamma, 0) \subset (C^2, 0)\) does not satisfy Condition \((\ast 2)\) of Theorem 4.5, i.e., there exists two components \(\delta_1\) and \(\delta_2\) of the lifting \(\ell^{-1}(\gamma)\) such that \(q > q_\delta\), where \(q_\delta\) is defined as in Condition \((\ast 2)\) and \(q\) equals the contact exponent \(q_{\ell(\delta_1)}, \ell(\delta_2)\).

Now lift the arc \(p\) defined before to two semi-algebraic arcs \(\gamma_1: [0, 1] \to \delta_1\) and \(\gamma_2: [0, 1] \to \delta_2\). We then have \(d_{out}(\gamma_1(t), \gamma_2(t)) = O(t^{q_\delta})\). On the other hand, any path \(\sigma\) in \(X\) from \(\gamma_1(t)\) to \(\gamma_2(t)\) corresponds to a path \(\hat{\sigma}\) in the resolution graph \(\Gamma\) joining the vertices \(v_1\) and \(v_2\). By the same argument as before, the length of a minimal \(\sigma\) will be \(O(t^{q_\delta})\) where \(q_\delta\) is the minimal rate of the vertices on \(\hat{\sigma}\). Therefore \(d_{inn}(\gamma_1(t), \gamma_2(t)) = O(t^{q_\delta})\) and we conclude as before that \((X, 0)\) is not Lipschitz normally embedded.

Therefore, if \((X, 0)\) is Lipschitz normally embedded, then any test curve \((\gamma, 0) \subset (C^2, 0)\) satisfies conditions \((\ast 1)\) and \((\ast 2)\).

We now want to prove that, conversely, if any test curve satisfies conditions \((\ast 1)\) and \((\ast 2)\), then \((X, 0)\) is Lipschitz normally embedded.

Let \(\ell_1, \ell_2\) and \(\ell_3: (X, 0) \to (C^2, 0)\) be three distinct generic projections for \((X, 0)\) and for \(i = 1, 2, 3\), let \(A_i\) be a polar wedge for \(\ell_i\) such that \(A_1\), \(A_2\) and \(A_3\) are pairwise disjoint outside the origin. Then for any pair of points \(p, q \in X - \{0\}\) sufficiently close to \(0\), \(p\) and \(q\) are both outside \(A_i\) for at least one of \(i \in \{1, 2, 3\}\). Choose such an \(i\) and set \(\ell_{(p, q)} = \ell_i\).

By a straightforward adaptation of the argument in the last page of [20], one shows that there exist a neighborhood \(V\) of \(0\) in \(X\) and a constant \(L \geq 1\) such that for any pair \(p, q \in V\),

\[
\frac{1}{L} \left( d_{inn}(p, q') + d_{out}(q', q) \right) \leq d_{out}(p, q)
\]

where \(q'\) is the extremity of the lifting by \(\ell = \ell_{(p, q)}\) of the segment \([\ell(p), \ell(q)]\) with origin \(p\). In particular, \(\ell(q') = \ell(q)\).

Thus the result follows from the following Lemma 4.8 which is proved later. □

**Lemma 4.8.** Let \(\ell: (X, 0) \to (C^2, 0)\) be a generic projection for \((X, 0)\) and let \((A, 0)\) be a polar wedge for \(\ell\). Assume that any test curve for \(\ell\) satisfies conditions \((\ast 1)\) and \((\ast 2)\). Then there exists \(\epsilon > 0\) and a constant \(K \geq 1\) such that for any
Let $\pi \in B^2 \setminus \{0\}$ and any pair of distinct points $p_1, p_2 \in X \setminus A$ such that $\ell(p_1) = \ell(p_2)$, we have $d_{in}(p_1, p_2) \leq Kd_{out}(p_1, p_2)$.

In order to prove Lemma 4.8, we need two preliminary lemmas 4.9 and 4.10.

Lemma 4.9. Let $\gamma$ be a test curve. Then Condition (\dagger) implies that the restriction of $\ell$ to any component $\delta$ of $\ell^{-1}(\gamma)$ is an isomorphism.

Proof. Let $C_{\psi}$ be the irreducible component of $\rho^{-1}(0)$ such that $\gamma^*$ is a generic curve of $C_{\psi}$. Then $B = \rho(N(C_{\psi}))$ is a $B(q_{\gamma})$-piece. Let $\hat{B}$ be the component of $\ell^{-1}(B)$ which contains $\delta$ (by a component of a semi-algebraic germ $(Z, 0)$, we mean the closure of a connected component of $Z \setminus \{0\}$).

Let $\ell' : (X, 0) \to (\mathbb{C}^2, 0)$ be another generic projection and let $\Delta'$ be its discriminant curve. Then $\ell'([B])$ is up to higher order a $B(q_{\gamma})$-piece of a carousel decomposition of $\Delta'$. Choose a generic test curve $\gamma'$ in it and let $\delta'$ be the component of the lifting $\ell'^{-1}(\gamma')$ inside $B$.

Let $y = \sum_{a_1} a_1 x^{a_1}$ be a Puiseux expansion of $\gamma$. Since the curve $\ell(\delta')$ is inside $B$ and $\hat{B}$ is a $q_{\gamma}$-neighbourhood of $\gamma$, then the Puiseux expansion of $\ell(\delta')$ coincides with that of $\gamma$ up to exponent $q_1 q_{\gamma}$, with a distinct non zero coefficient for $x^{q_{\gamma}}$.

Assume $\ell |_{\delta} : \delta \to \gamma$ is not an isomorphism, then $\text{mult}(\delta) = k \text{mult}(\gamma)$ where $k$ is an integer $\geq 2$. Since the curves $\delta$ and $\delta'$ are isomorphic, then $\text{mult}(\delta) = \text{mult}(\delta')$. Since $\ell$ is generic for $\delta'$, then $\text{mult}(\ell(\delta')) = \text{mult}(\delta')$. So we get $\text{mult}(\ell(\delta')) = k \text{mult}(\gamma)$. Since $q_{\gamma}$ is the greatest characteristic Puiseux exponent of $\gamma$ and since the Puiseux expansions of $\gamma$ and $\ell(\delta')$ coincide up to exponent $q_{\gamma}$, we then obtain that $\ell(\delta')$ admits a characteristic exponent $q > q_{\gamma}$. Since $\delta$ and $\delta'$ are isomorphic, $q$ is an outer rate of $\gamma$ and Condition (\dagger) is not satisfied.

Let $\pi : \tilde{X} \to X$ be a resolution of $(X, 0)$ described after Definition 3.2. It factors through the Nash modification $\nu : \tilde{X} \to X$ and through the blow-up of the origin and no two nodes of its resolution graph $\Gamma$ are adjacent. Let $\sigma : \tilde{X} \to \mathbb{G}(2, n)$ be the map induced by the projection $p_2 : \tilde{X} \subset X \times \mathbb{G}(2, n) \to \mathbb{G}(2, n)$. The map $\sigma$ is well defined on $E = \pi^{-1}(0)$ and its restriction to $E$ is constant on any connected component of the complement of the complement of $E$ (\cite{[11]} Section 2), \cite{[22]} Part III, Theorem 1.2). The connected subgraphs of $\Gamma$ obtained by removing all $\mathcal{P}$-nodes and adjacent edges are called $\mathcal{P}$-Tjurina components.

Lemma 4.10. Let $\gamma$ be a test curve and $\delta_1$ and $\delta_2$ two components of $\ell^{-1}(\gamma)$ whose strict transforms meet $E_1$ and $E_2$ at smooth points $p_1$ and $p_2$ of $E$.

Assume $E_1$ and $E_2$ are not $\mathcal{P}$-curves and that there exists a path in the graph of $\pi$ joining $v_1$ to $v_2$ through vertices with rates $\geq q_{\gamma}$. Then Condition (\ddagger) implies $\sigma(p_1) \neq \sigma(p_2)$.

Proof. Consider a semi-algebraic arc $p : [0, 1) \to \gamma$ such that $||p(t)|| = O(t)$ and two distinct liftings $\gamma_1 : [0, 1) \to \delta_1$ and $\gamma_2 : [0, 1) \to \delta_2$ of $p$ by $\ell$. Then $d_{out}(\gamma_1(t), \gamma_2(t)) = O(t^q)$ where $q$ is an outer rate of $\gamma$.

For $q' > q_{\gamma}$ sufficiently close to $q_{\gamma}$, there exists an $A(q_{\gamma}, q')$-piece $A$ such that $\gamma$ is in the outer boundary of $A$ and $A \cap \Delta = \emptyset$. Let $A_1$ and $A_2$ be the liftings of $A$ containing respectively $\delta_1$ and $\delta_2$. $A_1$ and $A_2$ are inside $N(\Gamma_1)$ and $N(\Gamma_2)$ where $\Gamma_1$ and $\Gamma_2$ are the $\mathcal{P}$-Tjurina components containing $v_1$ and $v_2$. Assume
\[ \sigma(p_1) = \sigma(p_2). \] Adapting the arguments of the proof of Lemma 11.7 in [20] inside the pieces \( A_1 \) and \( A_2 \), one obtains

\[
\lim_{t \to 0} \frac{d_{\text{inn}}(\gamma_1(t), \gamma_2(t))}{d_{\text{out}}(\gamma_1(t), \gamma_2(t))} = \infty.
\]

This contradict Condition (\( \ast_2 \)) (here \( q_0 = q_1 \)). \( \square \)

**Remark 4.11.** A consequence of Lemma 4.10 is that for any \( \mathcal{P} \)-Tjurina component \( \Gamma' \), \( \pi(N(G')) \) contains at most one component of \( \ell^{-1}(\gamma) \).

**Proof of Lemma 4.8.** Consider a \( B(q) \)-piece \( B \) of the carrousel decomposition of \( \mathbb{C}^2 \) with respect to the discriminant curve \( \Delta \) of \( \ell \). Let \( N_1 \) and \( N_2 \) be two components of \( \ell^{-1}(B) \), so \( N_1 \) and \( N_2 \) are \( B(q) \)-pieces, possibly with \( N_1 = N_2 \). Let \( q_0 \) be the maximum among minimum of inner rates of pieces along paths joining \( N_1 \setminus \{0\} \) to \( N_2 \setminus \{0\} \) in \( X \setminus \{0\} \), so \( q_0 < q \) and \( q_0 = q \) if and only if \( N_1 = N_2 \) or \( N_1 \) or \( N_2 \) can be joined by a path through pieces with higher rates.

**Claim 1.** There exists \( K_1, K_2 > 0 \) and \( \epsilon > 0 \) such that for all \( p \in (B^4_q \setminus \{0\}) \cap B \) and for all any pair of distinct points \( p_1, p_2 \) such that \( p_1 \in (N_1 \setminus A) \cap \ell^{-1}(B^4_q) \),\( p_2 \in (N_2 \setminus A) \cap \ell^{-1}(B^4_q) \) and \( \ell(p_1) = \ell(p_2) = p \), we have

\[
d_{\text{inn}}(p_1, p_2) \leq K_1 ||p||^{q_0},
\]

and

\[
K_2 ||p||^{q_0} \leq d_{\text{out}}(p_1, p_2).
\]

A straightforward consequence of Claim 1 is that for all \( p \in (B^4_q \setminus \{0\}) \cap B \) and \( p_1, p_2 \) as before,

\[
\frac{d_{\text{inn}}(p_1, p_2)}{d_{\text{out}}(p_1, p_2)} \leq \frac{K_1}{K_2}.
\]

**Proof of Claim 1.** Choose coordinates \( (x, y, z, \ldots) \) in \( \mathbb{C}^n \) such that \( \ell = (x, y) \) and the piece \( B \) is foliated by test-curves \( \gamma_\alpha \) with Puiseux expansions

\[
y = \sum_{i=1}^{k} a_i x^{p_i} + \alpha x^{q}
\]

where \( p_1 < p_2 < \ldots < p_k < q \) and where \( \alpha \) is in a compact set \( W \subset \mathbb{C} \).

For any \( q' \geq 1 \), if a projection \( \ell' \) is generic for a curve \( \delta \) then it is generic for any curve in a \( q' \)-neighbourhood of \( \delta \). Since \( W \) is compact, one can choose a finite number of projections \( \ell_1, \ldots, \ell_s \) and a decomposition \( W = W_1 \cup \ldots \cup W_s \) into compact sets such that for any \( \alpha \in W_j \), \( \ell_j \) is generic for \( \ell^{-1}(\gamma_\alpha) \). We will assume \( s = 1 \) since the proof is similar for \( s \geq 2 \) taking minimums of bounds. So we choose \( \ell_1 \) such that for each \( \alpha \in W \), the projection \( \ell_1 \) is generic for \( \ell^{-1}(\gamma_\alpha) \) and we choose the coordinates \( (x, y, z, \ldots) \) in \( \mathbb{C}^n \) so that \( \ell_1 = (x, z) \).

Let \( \alpha \in W \) and let \( p \in \gamma_\alpha \cap (B^4_q \setminus \{0\}) \). By Lemma 4.9, two distinct points \( p_1 \) and \( p_2 \) such that \( \ell(p_1) = \ell(p_2) = p \) belong to distinct connected components of the lifting \( \ell^{-1}(\gamma_\alpha) \).

Let \( \delta^{(1)}_\alpha \subset N_1 \) and \( \delta^{(2)}_\alpha \subset N_2 \) be two distinct irreducible components of the lifting \( \ell^{-1}(\gamma_\alpha) \) such that \( \delta^{(1)}_\alpha \cap A = \delta^{(2)}_\alpha \cap A = \{0\} \) and \( \delta^{(1)}_\alpha \neq \delta^{(2)}_\alpha \) if \( N_1 = N_2 \).
Since $\ell_1$ is generic for $\delta_2^{(1)} \cup \delta_2^{(2)}$, Condition (**) implies that the curves $\ell_1(\delta_2^{(1)})$ and $\ell_1(\delta_2^{(2)})$ have Puiseux expansions respectively:

$$z = \sum_{j=1}^{m} b_j(\alpha)x^{r_j} + b_0^{(1)}(\alpha)x^{q_0} + h.\alpha,$$

and

$$z = \sum_{j=1}^{m} b_j(\alpha)x^{r_j} + b_0^{(2)}(\alpha)x^{q_0} + h.\alpha,$$

where

- $r_1 < r_2 < \ldots < r_m < q_0$,
- $b_j(\alpha), j = 1, \ldots, m, b_0^{(1)}(\alpha)$ and $b_0^{(2)}(\alpha)$ depend continuously on $\alpha$,
- for all $\alpha \in W$, $b_0^{(1)}(\alpha) \neq b_0^{(2)}(\alpha)$,

and where "$+h.\alpha$" means plus higher order terms.

Let $\overline{p} = (x,y) \in \delta_2^{(1)}$ and $\overline{p}_1 \in \delta_2^{(1)}$ and $\overline{p}_2 \in \delta_2^{(2)}$ such that $\ell(\overline{p}_1) = \ell(\overline{p}_2) = \overline{p}$. Since $||\overline{p}|| = O(|x|)$, there exists $L \geq 1$ such that:

$$\frac{1}{L} |b_0^{(1)}(\alpha) - b_0^{(2)}(\alpha)| \cdot ||\overline{p}||^{q_0} \leq ||\ell(\overline{p}_1) - \ell(\overline{p}_2)|| \leq d_{out}(\overline{p}_1, \overline{p}_2).$$

Since $W$ is compact, there exists $K'_2 > 0$ such that for all $\alpha \in W$, $K'_2 \leq \frac{1}{L} |b_0^{(1)}(\alpha) - b_0^{(2)}(\alpha)|$. Taking the minimum $K_2$ of $K'_2$ among all pairs $\delta^{(1)}_2, \delta^{(2)}_2$ as before, there exists $\epsilon > 0$ such that for all $\overline{p} \in (B^4 \setminus \{0\}) \cap B$ and for $\overline{p}_1$ and $\overline{p}_2$ as before,

$$K_2 ||\overline{p}||^{q_0} \leq d_{out}(\overline{p}_1, \overline{p}_2).$$

Let us now bound $d_{inn}(\overline{p}_1, \overline{p}_2)$.

We consider the carrousel decomposition of $C^2$ with respect the the discriminant curve $\Delta$ of $\ell$ and we decompose $X$ into pieces consisting of components of inverse images by $\ell$ of pieces of the decomposition of $C^2$ (see also end of Section 3).

Since $\overline{p}_1$ and $\overline{p}_2$ are on different sheets of the cover $\ell$, a path from $\overline{p}_1$ to $\overline{p}_2$ with minimal length will have to travel through a $B(q_0)$-piece of $(X,0)$ and it only travels through pieces with rates $\geq q_0$. Now $\ell(N)$ is a $B(q_0)$-piece in $(C^2,0)$ and there exists $a > 0$ such that $\epsilon > 0$ sufficiently small, if $(x,y_1)$ and $(x,y_2)$ are in $\ell(N) \cap B^4$ then $|y_1 - y_2| \leq a|x|^{q_0}$.

Let $m = m(X,0)$ (so $m$ is at most the order of the cover $\ell|_N$: $N \rightarrow \ell(N)$), and let $\kappa$ be the local bilipschitz constant of $\ell$ outside the polar wedge $A$. Then $d_{inn}(\overline{p}_1, \overline{p}_2)$ is less than or equal to $m\kappa$ times the diameter of $\ell(N)$ providing one avoids the $\Delta$-wedge $\ell(A)$. So we obtain

$$d_{inn}(\overline{p}_1, \overline{p}_2) \leq m(\pi a)\kappa||p||^{q_0},$$

where we use the factor $\pi a$ instead of $a$ to allow replacing a segment by a path avoiding $\ell(A)$. Setting $K_1 = m(\pi a)\kappa$ completes the proof of Claim 1. $\Box$

Let us now consider an $A(q, q')$-piece $A_0$ of the carrousel decomposition of $C^2$ with respect to $\Delta$ with $q < q'$, so $A_0 \cap \Delta = \emptyset$. According to Lemma 4.9 and Remark 4.11 if $A'$ is a component of $\ell^{-1}(A_0)$, the restriction $\ell|_{A'}: (A',0) \rightarrow (A_0,0)$ is a homeomorphism and two distinct components of $\ell^{-1}(A_0)$ have distinct corresponding $P$-Tjurina components.

Let $A_1$ and $A_2$ be two distinct components of $\ell^{-1}(A_0)$, so $A_1$ and $A_2$ are $A(q, q')$-pieces. Let $q_0$ be the maximum among minimum of inner rates of pieces along paths
joining $A_1 \setminus \{0\}$ to $A_2 \setminus \{0\}$ in $X \setminus \{0\}$. (So $q_0 \leq q$ and $q_0 = q$ if and only if $A_1$ or $A_2$ can be joined by a path through pieces with rates $\geq q_0$.)

**Claim 2.** There exists $K > 0$ and $\epsilon > 0$ such that for all $p \in (B^4_1 \setminus \{0\}) \setminus A_0$ and for all $\mathfrak{a}_1 \in A_1 \cap \ell^{-1}(B^4_2)$ and $\mathfrak{a}_2 \in A_2 \cap \ell^{-1}(B^4_1)$ such that $\ell(\mathfrak{a}_1) = \ell(\mathfrak{a}_2) = p$, we have

$$\frac{d_{inn}(\mathfrak{a}_1, \mathfrak{a}_2)}{d_{out}(\mathfrak{a}_1, \mathfrak{a}_2)} \leq K.$$

**Proof of Claim 2.** Let $\Gamma_1$ and $\Gamma_2$ be the $\mathcal{P}$-$\text{Tjurina}$ components such that $A_i \subset \pi(N(\Gamma_i))$, $i = 1, 2$. Let $P_1$ (resp. $P_2$) be the values of $\sigma$ on $\bigcup_{v_j \in \Gamma_1} E_j$ (resp. $\bigcup_{v_j \in \Gamma_2} E_j$).

In suitable coordinates the semi-algebraic set $A_0$ is defined by inequalities

$$\alpha |x|^q \leq |y| - \sum_{i=1}^k a_i |x^{p_i}| \leq \alpha |x|^q,$$

where $\alpha > 0$ and $1 \leq p_1 < p_2 < \ldots < p_k = q$.

Let $n = \text{lcm}(\text{denom}(q), \text{denom}(p_i), i = 1, \ldots, k)$. Then $A_0$ is the union of the images of the maps $\phi_{\xi_1, \xi_2} : [0, 1] \times [0, 1] \rightarrow (\mathbb{S}^2, 0)$ parametrized by $(\xi_1, \xi_2) \in S^1 \times S^1$ and defined by

$$\forall (s, t) \in [0, 1] \times [0, 1], \quad \phi_{\xi_1, \xi_2}(s, t) = (x(t), y(s, t))$$

with

$$x(t) = \xi_1 t^n \quad \text{and} \quad y(s, t) = \sum_{i=1}^k a_i x(t)^{p_i} + \alpha \xi_2 \left( sx(t)^q + (1 - s) x(t)^q \right)$$

Notice that $||\phi_{\xi_1, \xi_2}(s, t) || = O(t^n)$.

**Case 1.** Assume first that $A_1$ or $A_2$ can be joined by a path through pieces with rates $\geq q'$.

Fix $\xi_1, \xi_2 \in S^1 \times S^1$ and consider two liftings $\phi_1 : [0, 1] \times [0, 1] \rightarrow A_1$ and $\phi_2 : [0, 1] \times [0, 1] \rightarrow A_2$ of $\phi$ by $\ell$. i.e., $\phi_1 = (\ell|A_1)^{-1} \circ \phi_{\xi_1, \xi_2}$ and $\phi_2 = (\ell|A_2)^{-1} \circ \phi_{\xi_1, \xi_2}$. Let $(c_{s,t})$ be a continuous family of paths in $X \setminus \{0\}$ parametrized by $(s, t) \in [0, 1] \times (0, 1)$ such that,

- $c_{s,t}$ has origin $\phi_1(s, t)$ and extremity $\phi_2(s, t)$
- $c_{s,t}$ consists of the path $\phi_1([s, 1] \times \{t\})$ followed by a path $c'_i$ from $\phi_1(1, t)$ to $\phi_2(1, t)$ (independent of $s$) through pieces with rates $> q'$ followed by the reversed $\phi_2((s, 1] \times \{t\})$.

Fix $s \in [0, 1)$. As $t$ tends to 0, the ratio $\frac{\text{length}(c'_i)}{\text{length}(\phi_1([s, 1] \times \{t\}))}$ tends to zero for $i = 1, 2$ and the path $c_{s,t}$ tends to the union of two segments whose angles with the kernel of $\ell$ depends only on $P_1$ and $P_2$ (see Figure 1). Since $P_1 \neq P_2$ (Lemma 4.10) and since the projection $\ell$ is generic, we obtain that for all $s \in [0, 1)$$

$$\lim_{t \rightarrow 0} \frac{\text{length}(c_{s,t})}{d_{out}(\phi_1(s, t), \phi_2(s, t))} = a,$$

where $a > 0$ just depends on $P_1$ and $P_2$ (so it is independent of $\xi_1, \xi_2$ and $s$). Since $d_{inn}(\phi_1(s, t), \phi_2(s, t)) \leq \text{length}(c_{s,t})$, this proves Claim 2 in that case.

**Case 2.** Assume now that any path from $A_1$ or $A_2$ goes through pieces with rates $\leq q$. Let $B$ (resp. $B'$) be the $B(q)$-piece (resp. $B(q')$-piece) attached to the outer
(resp. inner) boundary of $A_0$ and let $\epsilon$, $K_1$ and $K_2$ (resp. $K'_1$ and $K'_2$) be constants associated to $B$ (resp. $B'$) as in Claim 1.

Fix $\xi_1, \xi_2 \in S^1 \times S^1$ and consider again $\phi_1$ and $\phi_2$ as defined in Case 1. We have for all $(s, t) \in [0, 1] \times (0, 1),$

$$d_{\text{inn}}(\phi_1(s, t), \phi_2(s, t)) \leq d_{\text{inn}}(\phi_1(0, t), \phi_2(0, t)) +$$

$$\text{length}(\phi_1([0, s] \times \{t\})) + \text{length}(\phi_2([0, s] \times \{t\}))$$

Let $\epsilon > 0$ be sufficiently small and let $\kappa > 0$ be a bound for the local bilipschitz constant of the restriction $\ell : X \cap \ell^{-1}(B_\epsilon) \times A \rightarrow B_\epsilon$, where $A$ is a polar wedge around the polar curve of $\ell$. We then have for $t$ sufficiently small, i.e., such that $\phi_{\xi_1, \xi_2}(s, t) \in B_\epsilon$,

$$d_{\text{inn}}(\phi_1(s, t), \phi_2(s, t)) \leq d_{\text{inn}}(\phi_1(0, t), \phi_2(0, t)) + 2\kappa \alpha s(t^{nq} - t^{nq'}) \leq K''_1 t^{nq'},$$

where $K''_1 = K_1 + 2\kappa \alpha$. Notice that $K''_1$ is independent of $\xi_1, \xi_2$ and $s$. Since $||\phi_{\xi_1, \xi_2}(s, t)|| = O(t^n)$, we then have proved that there exist a constant $C > 0$ and $\epsilon > 0$ such that for any $\underline{p} \in B_\epsilon \cap A_0$,

$$d_{\text{inn}}(\underline{p}_1, \underline{p}_2) \leq C||\underline{p}||^{\rho_0}$$

where $\underline{p}_1$ and $\underline{p}_2$ are the liftings of $\underline{p}$ to $A_1$ and $A_2$ respectively.

Let us now deal with the outer distance. As $t$ tends to 0, the two arcs $\phi_1([0, 1] \times \{t\})$ and $\phi_2([0, 1] \times \{t\})$ tend to the union of two coplanar segments which are opposite sides of a trapezoid (Figure 2). Then for $t > 0$ sufficiently small and for any $s \in [0, 1],$

$$d_{\text{out}}(\phi_1(s, t), \phi_2(s, t)) \geq (1 - \eta) \min\left(d_{\text{out}}(\phi_1(0, t), \phi_2(0, t)), d_{\text{out}}(\phi_1(1, t), \phi_2(1, t))\right)$$

with $\eta$ small (the constant $1 - \eta$ is for the case when $P_1 = P_2$ in the previous notation, i.e., the trapezoid is a rectangle).

Applying Claim 1 to the pieces $B$ and $B'$ adjacent to $A_0$, there exist $K_2 > 0$ and $K'_2 > 0$ such that for all $t > 0$ sufficiently small,

$$K_2||\phi_{\xi_1, \xi_2}(0, t)||^{\rho_0} \leq d_{\text{out}}(\phi_1(0, t), \phi_2(0, t)),$$

and

$$K'_2||\phi_{\xi_1, \xi_2}(1, t)||^{\rho_0} \leq d_{\text{out}}(\phi_1(1, t), \phi_2(1, t)).$$
Since for all \( s, ||\phi_{\xi_1,\xi_2}(s,t)|| = O(t^n) \), we then obtain that there exists \( C' > 0 \) and \( \epsilon > 0 \) such that for any \( p \in B_{\epsilon} \),

\[
C' ||p||^{q_0} \leq d_{out}(p_1, p_2).
\]

where \( p_1 \) and \( p_2 \) are the liftings of \( p \) to \( A_1 \) and \( A_2 \) respectively. This proves Claim 2 in Case 2.

---

Claim 1 and Claim 2 imply Lemma 4.8.

---

5. The geometric decomposition of a minimal singularity

The aim of this section is to describe the geometric decomposition with rates of a minimal surface singularity germ \((X,0)\) and its correspondence with the carousel decomposition of \((\mathbb{C}^2,0)\) with respect to the discriminant curve \(\Delta\) of a generic projection of \((X,0)\) and the resolution \(\rho\) of \(\Delta\) (see Section 4).

Let us first recall the definition of the minimal (also called fundamental) cycle \(Z_{\text{min}}\) of a normal surface singularity \((X,0)\). We refer to [18] for details. Let \(\pi: (\tilde{X}, E) \to (X,0)\) be a resolution and let \(E_1, \ldots, E_r\) be the irreducible components of the exceptional divisor \(E = \pi^{-1}(0)\). The minimal cycle \(Z_{\text{min}}\) is the minimal element of the set of divisors \(Z = \sum_{i=1}^r m_i E_i\) whose coefficients \(m_i\) are strictly positive integers and such that \(\forall j = 1, \ldots, r, Z : E_j \leq 0\). A reduced minimal cycle means that \(Z_{\text{min}} = \sum_i E_i\), i.e., \(m_i = 1\) for all \(i = 1, \ldots, r\).

If \(f: (X,0) \to (\mathbb{C},0)\) is an analytic function, then its total transform \((f) = (f \circ \pi)^{-1}(0)\) decomposes into \((f) = Z(f) + f^*\) where \(f^*\) is the strict transform and \(Z(f)\) a positive divisor with support on \(E\). For each \(j = 1, \ldots, r\), one has \((f) : E_j = 0\). Hence \(Z(f) : E_j \leq 0\) for all \(j = 1, \ldots, r\). If \(h: (X,0) \to (\mathbb{C},0)\) is a generic linear form, then \(Z(h)\) is the minimal element among divisors \(Z(f)\), and \(Z_{\text{min}} \leq Z(h)\). For any rational singularity, a fortiori for minimal, the minimal resolution resolves the basepoints of the family of generic linear forms and \(Z(h) = Z_{\text{min}}\) (see [1, 18]). So, for a rational singularity, the \(L\)-nodes in a resolution graph, and then, the thick-thin decomposition, are topologically determined.

We now restrict to minimal singularities. In order to describe the geometric decomposition of \((X,0)\), we will use the description by Spivakovsky [22] of the minimal resolution \(\pi\) of the pencil of polar curves of generic plane projections \((X,0) \to (\mathbb{C}^2,0)\) and the description by Bondil [2] of the resolution \(\rho\) of the
family of projected polars $\ell(\Pi_\mathcal{D})$, where $\ell: (X, 0) \to (\mathbb{C}^2, 0)$ is a generic plane projection.

In [24], Spivakovsky gives the following combinatorial characterization of the dual resolution graphs of minimal singularities which immediately furnishes the $\mathcal{L}$-nodes. Let $\pi': X' \to X$ be the the minimal good resolution of $(X, 0)$ and let $\Gamma'$ be its dual graph. Denote by $V(\Gamma')$ the set of vertices of $\Gamma'$. If $v \in V(\Gamma')$, we denote by $E_v$ the corresponding irreducible component of the exceptional divisor $(\pi')^{-1}(0)$, we set $w(v) = E_v^2$ and we denote by $\nu(v)$ the valence of $v$, i.e., the number of edges adjacent to $v$.

**Proposition 5.1.** [22] A surface singularity is minimal if and only if $\Gamma'$ is a tree of rational curves and for all vertices $v \in V(\Gamma')$, $-w(v) \geq \nu(v)$.

**Remark 5.2.** Since the minimal cycle is reduced, a vertex of $\Gamma'$ is an $\mathcal{L}$-node if and only if $-w(v) > \nu(v)$.

Spivakovsky introduced the function $s: V(\Gamma') \to \mathbb{N}$ defined as follows: $s(v)$ is the number of vertices on the shortest path from $v$ to an $\mathcal{L}$-node. So $s(v) = 1$ if and only if $v$ is an $\mathcal{L}$-node.

Since minimal singularities are rational they can be resolved by only blowing up points, as Tjurina showed in [24], and $s(v)$ is the number of blow-ups it takes before $E_v$ appears in the successive exceptional divisors.

We now state Theorem 5.4 in Chapter III of [22] in a formulation inspired by Bondil in [2].

**Theorem 5.3.** [24] Chap. III, Theorem 5.4] Let $(X, 0)$ be a minimal surface singularity. Let $\ell: (X, 0) \to (\mathbb{C}^2, 0)$ be a generic linear projection and let $\Pi$ be its polar curve. Let $\pi': (X', 0) \to (X, 0)$ be the minimal resolution of $(X, 0)$. Consider the cycle $S := \sum s(v)E_v$, where the $E_v$ are the irreducible components of $(\pi')^{-1}(0)$.

Then the strict transform $\Pi^*$ of $\Pi$ by $\pi'$ is smooth. It consists of exactly $-\left(S + E_v\right)\cdot E_v + 2$ curvettes of each $E_v$ and one component through each intersection point $E_v \cap E_w$ for which $s(v) = s(w)$. Moreover, the latter intersection points are the only basepoints of the family of generic polars $\Pi_\mathcal{D}$, and they are simple, i.e., they are resolved by one blow-up.

Following the terminology of [22], an edge of $\Gamma'$ between two vertices $v$ and $w$ is central if $s(v) = s(w)$, and a vertex $v$ is central if there are at least two neighboring vertices $w, w'$ such that $s(v) - 1 = s(w) = s(w')$. Using this, the above theorem says that for each central edge there is one component of $\Pi^*$ through the intersection point of the corresponding curves and that for each central vertex $v$, there is at least one component of $\Pi^*$ which is a curvette of $E_v$. Any other components of $\Pi^*$ go through $\mathcal{L}$-nodes.

In [2], Bondil shows that the minimal resolution of $(X, 0)$ obtained by only blowing up points is also the minimal resolution of $\Pi$ just described. Then, blowing up the points corresponding to central edges, we get the resolution $\pi_0: (\tilde{X}_0, E) \to (X, 0)$ introduced in Section 3 i.e., the minimal resolution which factors through the blow-up of the origin and through Nash blow-up.

We then know the resolution graph $\Gamma_0$ of $\pi_0$ together with its nodes. So we topologically know the geometric decomposition of $(X, 0)$ from the resolution graph. We now need to determine the rate $q$ of each node. In order to do this, we will use a more precise description of the polar curve and of the discriminant curve presented by Bondil in [2].
An $A_n$-curve is a germ of an analytic curve isomorphic to the plane curve $y^2 + x^{n+1} = 0$. If $n$ is odd, then $A_n$ consists of a pair of smooth curves with contact exponent $\frac{n+1}{2}$ while if $n$ is even, $A_n$ is an irreducible curve.

**Theorem 5.4** ([2, 3]). Let $(X, 0)$ be a minimal singularity, and let $\Pi$ be the polar of a generic linear projection. Then

1. $\Pi$ decomposes as a union of $A_{n_i}$-curves $\Pi = \bigcup_i C_i$ and each $C_i$ meet a single irreducible component $E_{v_i}$ of the exceptional divisor of $\pi_0$.
2. If $E_{v_i}^2 = -1$ (i.e., $E_{v_i}$ comes from blowing up a central edge), then $C_i$ is an irreducible $A_{2s(v_i) - 2}$-curve. Otherwise $C_i$ consists of two smooth curves forming an $A_{2s(v_i) - 1}$-curve.
3. The contact exponent between $C_i$ and $C_j$ equals the minimal value of $s(v)$ on the shortest path in $\Gamma_0$ between the vertices $v_i$ and $v_j$.

Using the fact that each branch of $\Pi$ is isomorphic to a plane curve and that the restriction $\ell \mid \Pi : \Pi \to \Delta$ is generic, Bondil deduces from Theorem 5.4 the following description of the discriminant curve:

**Proposition 5.5** ([2, 3]). The discriminant curve $\Delta$ of a generic projection $\ell$ of $(X, 0)$ is a union of $A_{n_i}$-curves in one-to-one correspondence with the curves $C_i$ of Proposition 5.4, and their pairwise contact exponents equal that of the corresponding $C_i$'s. Moreover, the minimal resolution of $\Delta$ is the resolution $\rho : Y \to \mathbb{C}^2$ which resolves the base points of the family of generic polar curves $(\ell(\Pi_D))_{D \in \Omega}$.

We deduce from this the rates of the pieces $B(q)$ of the geometric decomposition of $(X, 0)$:

**Corollary 5.6.** Let $(X, 0)$ be a minimal surface singularity and let $\Gamma_0$ be the dual resolution graph of the resolution $\pi_0$ described above. The rate $q_v$ of a node $v$ of $\Gamma$ is given by:

$$q_v = \begin{cases} s(v) & \text{if } E_{v_i}^2 < -1 \\ s(v) - 1/2 & \text{if } E_{v_i}^2 = -1, \end{cases}$$

**Proof.** The rate $q_v$ is the contact exponent between the $\pi$-images of two generic curvettes of $E_v$. When $v$ is a node such that $E_{v_i}^2 < -1$, the images of two generic curvettes of $E_v$ form a $A_{2s(v) - 1}$-curve so their contact exponent equals $s(v)$. When $E_{v_i}^2 = -1$ the images of two generic curvettes of $E_v$ are $A_{2s(v) - 2}$-curves whose contact exponent equals $s(v) - 1/2$. □

**Example 5.7.** Let $(X, 0)$ be a minimal singularity with the following resolution graph:

```
   -4 -2 -3 -3 -2 -2
   O     O     O     O
   -2 -2 -2
   -2
```

We deduce from this the rates of the pieces $B(q)$ of the geometric decomposition of $(X, 0)$.
The negative weights are the self-intersections of the exceptional curves. The \( L \)-nodes are the vertices \( v \) such that \(-w(v) > \nu(v)\) (Remark 5.2). They are in black in the graph.

The following graph on the left shows two different things. First, the arrows represent the components of the polar curve of a generic plane projection. The gray node represents a curve obtained by blowing up the minimal resolution at the intersection point of two exceptional curves corresponding to a central edge. There are four pairs \( C_1, \ldots, C_4 \) of smooth components, and one component \( C_5 \) with multiplicity 2. Secondly, it shows the geometric decomposition of \((X, 0)\). The rational numbers in italics are the rates of the nodes.

The graph on the right is the resolution graph of the discriminant curve \( \Delta = \ell(\Pi) \). The arrows represent the components of \( \Delta = \bigcup_{i=1}^{5} \Delta_i \) where \( \Delta_i = \ell(\Pi_i) \), \( i = 1, \ldots, 5 \). The root-vertex is the black vertex and each vertex is weighted by the corresponding rate.

### 6. Minimal implies Lipschitz normally embedded

The aim of this section is to prove one direction of Theorem 1.2: any minimal surface singularity is Lipschitz normally embedded. We first state and prove the key Proposition 6.1.

Let \((X, 0)\) be a normal surface germ and let \( \ell: (X, 0) \to (\mathbb{C}^2, 0) \) be a generic projection. Let \( U \) be an open neighborhood of 0 in \( \mathbb{C}^2 \) and let \( e: U' \to U \) be the blow-up of the origin. Let \( X \) be the pull-back of \( \ell \) and \( e \) and let \( \tilde{\ell}: \tilde{X} \to U' \) and \( \tilde{e}: \tilde{X} \to X \) be the two projections. Let \( n: X' \to \tilde{X} \) be the normalization of \( \tilde{X} \). By [4, Prop. 2.15], \( e' = \tilde{e} \circ n \) is the normalized blowup of the maximal ideal of \((X, 0)\). We then have a commutative diagram:

When \((X, 0)\) is rational, a fortiori when minimal, \( e' \) is the blowup of the maximal ideal; no normalization is needed (24).
Proposition 6.1. Let \((X, 0)\) be a minimal surface singularity. Let \(\Pi\) be the polar curve of a generic projection \(\ell : (X, 0) \to (\mathbb{C}^2, 0)\) and let \(E' = e^{-1}(0)\). Choose \(p \in E'\) such that if it is a smooth point of \(X'\), then it is not on the strict transform \(\Pi^*\) of \(\Pi\). Set \(q := \ell'(p)\). Then

(i) the germ \((X', p)\) is a minimal singularity with multiplicity the number of irreducible components of \(E'\) through \(p\);

(ii) the map germ \(\ell' : (X', p) \to (U', q)\) is a generic projection for \((X', p)\).

 Remark 6.2. If \((X', p)\) is smooth and \(p \in \Pi^*\), then, according to \([2]\) either \((\Pi^*, p)\) is the strict transform of a moving polar (i.e., \(p\) is not a basepoint of the family of generic polars) or \((X, 0)\) is the singularity \(A_2 : x^2 + y^2 + z^3 = 0\). In both cases, it is easy to see that the degree of \(\ell'\) at \((X', p)\) equals 2 while the multiplicity of \((X, p')\) is 1. So \(\ell' : (X', p) \to (U', q)\) is not generic.

 Remark 6.3. The fact the \((X', p)\) is minimal is \([4]\) Théorème 5.9. The authors prove it there without using the existence of a resolution of \((X, 0)\). We give here a short proof using this fact.

Proof of Proposition 6.1. Let \(\pi : Y \to X\) be the minimal resolution of \((X, 0)\) and let \(\Gamma\) be its resolution graph. Since \((X, 0)\) is rational, then \(\pi\) factors through the blow-up of the maximal ideal \((\mathbb{C})\). Assume \((X', p)\) is not smooth. Then \((X', p)\) has minimal resolution graph one of the connected components \(\Gamma'\) of \(\Gamma\) minus the \(L\)-nodes. So \(\Gamma'\) is a rational graph and \((X', p)\) is rational. Moreover, since the minimal cycle of \((X, p)\) is reduced, the minimal cycle of \((X', p)\) is also reduced and the multiplicity \(m'\) of \((X', p)\) equals the number of \(L\)-nodes adjacent to \(\Gamma'\), i.e., the number of irreducible components of \(E'\) containing \(p\).

Assume now that \((X', p)\) is smooth. Then by hypothesis, \(p \notin \Pi^*\). Since there is a branch of \(\Pi^*\) through any singular point of \(E'\), it implies that \(p\) is a smooth point of \(E'\). So the number of branches of \(E'\) through \(p\) equals 1. This proves (i).

In order to prove (ii), we have to check that \(\ell' : (X', p) \to (U', q)\) satisfies Conditions (1) and (2) of Definition 2.2.

The map \(\ell' : X' \to U'\) is a branched cover with degree the multiplicity \(m = m(X, 0)\) of \((X, 0)\). Its discriminant locus is included in the strict transform \(\Delta^*\) of \(\Delta\) by \(e\) union the exceptional curve \(C = e^{-1}(0)\). This divisorial discriminant is computed in \([4]\) Proposition 6.1] for any normal surface germ \((X, 0)\): it equals \(\Delta^* + (m - r)C\) where \(r\) the number of branches of the generic hyperplane section of \((X, 0)\). In our case, \(r = m\) since \((X, 0)\) is minimal (\([4]\) Lemma 5.4 and Theorem 5.8 \)). So, the discriminant of \(\ell'\) is just the reduced curve \(\Delta^*\) and the branching locus of \(\ell'\) is \(\Pi^*\). In particular the polar curve of \(\ell' : (X', p) \to (U', q)\) is the germ \((\Pi^*, p)\).

Assume \((X', p)\) is smooth and \(p \notin \Pi^*\). Then \(\ell' : (X', p) \to (U', q)\) has empty polar curve, so it is an isomorphism and \(\ell' : (X', p) \to (U', q)\) is a generic projection. This proves (ii) in that case.

Assume now \((X', p)\) is not smooth. Then \(p \in \Pi^*\) since \((X, 0)\) is resolved by a sequence of blowing-ups of points on the successive strict transforms of \(\Pi\) (\([2]\) Lemma 3.1). Since the projection \(\ell\) is generic for its polar curve (Condition (1) of Definition 2.2), then the following Lemma 6.4 (which will be used again later) implies that \(\ell' : (X', p) \to (U', q)\) is a generic projection for its polar curve \((\Pi^*, p)\), i.e., it satisfies Condition (1) of Definition 2.2.
Lemma 6.4. Denote by \( e_0 : U_0 \to \mathbb{C}^N \) the blow-up of the origin of \( \mathbb{C}^N \) and let \((\gamma, 0) \subset (\mathbb{C}^N, 0)\) be a curve germ whose strict transform \( \gamma^* \) by \( e_0 \) intersects \( e_0^{-1}(0) \) at a unique point \( p \). Let \( \ell : \mathbb{C}^N \to \mathbb{C}^2 \) be a linear projection which is generic for the curve germ \((\gamma, 0)\).

We may choose coordinates so that \( \ell \) is the map \((z_1, \ldots, z_N) \mapsto (z_1, z_2)\). Denote by \( \mathbb{P}^{n-3} \) the subset of \( e_0^{-1}(0) \) given by \( z_1 = z_2 = 0 \). Let \( e : U' \to U \) be the blow-up of the origin of \( \mathbb{C}^2 \), where \( U \) is a neighborhood of 0. Then there is a map \( \ell_0 : (U_0 \setminus \mathbb{P}^{n-3}) \to U' \) with \( e \circ \ell_0 = \ell \circ e_0 \). By genericity of \( \ell \), the point \( p \) is in \( U_0 \setminus \mathbb{P}^{n-3} \).

Set \( q = \ell_0(p) \). Then the map germ \( \ell_0 : (U_0 \setminus \mathbb{P}^{n-3}, p) \to (U', q) \) is generic for the curve germ \((\gamma^*, p)\).

Proof. We will use the criterion of genericity introduced in the proof of Theorem 5.1 in [19]. Let us first assume that \((\gamma, 0)\) is irreducible and that the coordinates are chosen so that \((\gamma, 0)\) admits a Puiseux parametrization of the form

\[
\omega \mapsto (z_1(\omega), \ldots, z_N(\omega)) = (\omega^n, \sum_{j \geq n} a_{2j}\omega^j, \ldots, \sum_{j \geq n} a_{Nj}\omega^j)
\]

Set \( A := \{j : \exists i, a_{ij} \neq 0\} \) and call an exponent \( j \in A \setminus \{n\} \) an essential integer exponent if

\[
gcd\{i \in \{n\} \cup A : i \leq j\} < gcd\{i \in \{n\} \cup A : i < j\}.
\]

Denote by \( B \) the set of essential integer exponents of \((\gamma, 0)\).

**Genericity criterion** ([19, Section 5]) The projection \( \ell \) is generic for the curve germ \((\gamma, 0)\) if and only if \( B \subset \{j : a_{2j} \neq 0\} \).

We can assume our coordinates are chosen so that \((\gamma, 0)\) is tangent to the \( z_1 \)-axis and then \( A \subset \{j : j > n\} \). We consider for \( e_0 \) and \( e \) the chart over \( z_1 \neq 0 \) so that writing \((z_1, v_2, v_3, \ldots, v_N)\) the corresponding local coordinates of \( U_0 \) and \((z_1, v_2)\) that of \( U' \), we have: \( e_0(z_1, v_2, v_3, \ldots, v_N) = (z_1, z_1 v_2, z_1 v_3, \ldots, z_1 v_N) \) and \( e(z_1, v_2) = (z_1, z_1 v_2) \). Then \( q \) is the origin of the local coordinates of \( U_0 \) and the strict transform \( \gamma^* \) of \( \gamma \) by \( e_0 \) has the following Puiseux parametrization in the coordinates \((z_1, v_2, v_3, \ldots, v_N)\):

\[
\omega \mapsto (\omega^n, \sum_{j \geq n} a_{2j}\omega^j, \ldots, \sum_{j \geq n} a_{Nj}\omega^j)
\]

Since \( B \subset \{a_{2j} \neq 0\} \), the set of essential integer exponents of \( \gamma^* \) is \( \{j - n ; j \in B\} \). Since \( \ell_0 \) is given by \( \ell_0(z_1, v_2, v_3, \ldots, v_N) = (z_1, v_2) \), then, according to the above genericity criterion, \( \ell_0 \) is generic for \((\gamma^*, q)\).

The proof when \((\gamma, 0)\) is reducible is essentially the same using the extension of the genericity criterion in [19, Section 5] taking account of the contact exponents between branches. \( \square \)

Let us now prove that Condition (2) of Definition 2.2 is satisfied. Let \( \pi : \hat{X} \to X \) be the resolution introduced in Section 3. By definition, it factors through the blow-up \( e' \). Consider the map \( \pi' : \hat{X} \to X' \) defined by \( \pi = e' \circ \pi' \). According to Theorem 5.3, its restriction over \((X', p)\) is a resolution of \((X', p)\) which factors through the normalized Nash transform of \((X', p)\) and the \( \mathcal{P} \)-curves of \((X, 0)\) and \((X', p)\) over \( p \) coincide.

Now, take any \( D \subset \Omega \), where \( (\ell_D : (X, 0) \to (\mathbb{C}^2, 0))_{D \in \Omega} \) denotes the family of generic projections of \((X, 0)\). Let \( \ell'_D : (X', p) \to (\mathbb{C}^2, 0) \) be the projection defined
by $e \circ \ell'_D = \ell_D \circ e'$. We know that the polar curve $\Pi'_D$ of $\ell'_D$ equals the germ $(\Pi'_D, p')$ where * means strict transform by $e'$. Therefore the family of polars $(\Pi'_D)_{D \in \Omega}$ of projections $\ell'_D$ coincide with the family of germs $(\Pi'_D, p')_{D \in \Omega}$, which is equisingular in terms of strong simultaneous resolution. This shows that Condition \[2\] of Definition \[2.2\] is satisfied for the family $(\ell'_D)_{D \in \Omega}$. \[\square\]

We now prove the “if” direction of Theorem 1.2

Let $(X, 0)$ be a minimal surface singularity with generic projection $\ell: (X, 0) \to (C^2, 0)$. Let $\rho: Y \to C^2$ be the sequence of blow-ups which resolves the base points of the family of curves $(\ell(\Pi_D))_{D \in \Omega}$ and let $R$ be its resolution graph. We have to check Conditions (\ua{1.1}) and (\ua{2}) of Theorem 4.5 for any test curve $(\gamma, 0)$ associated to a node of $R$. In fact, we will check these conditions for the $\rho$-image of a curvette of any irreducible curve in $p^{-1}(0)$ (so any vertex of $R$, not only nodes). In the proof we say test curve for such a curve even if it correspond to a non node vertex.

By Proposition 5.5, the discriminant curve $\Delta$ of $\ell$ is a union of $A_n$-curves, and $\rho: Y \to C^2$ is the minimal resolution of $\Delta$. We consider the following two cases:

Case 1. $\gamma$ is the $\rho$-image of a curvette of $p^{-1}(0)$ whose inner rate $q_\gamma$ is an integer $n$ (in particular, $\gamma$ is smooth):

Case 2. $\gamma$ is the $\rho$-image of a curvette of $p^{-1}(0)$ such that $q_\gamma = n + 1/2$ with $n \geq 1$ an integer:

Case 1. We will proceed by induction on $q_\gamma$, so assume first $q_\gamma = 1$, i.e., $\gamma$ is a generic line through the origin of $C^2$, so $(\ell^{-1}(\gamma), 0)$ is a generic hyperplane section of $(X, 0)$. Since $(X, 0)$ is minimal, the generic hyperplane section $(\ell^{-1}(\gamma), 0)$ also has a minimal singularity (\[12\] Lemma 3.4.3) so it is a union of $m(X, 0)$ smooth transversal curves, where $m(X, 0)$ denotes the multiplicity of $(X, 0)$.

Therefore $\gamma$ has a single outer rate which equals 1 and Conditions (\ua{1.1}) and (\ua{2}) are satisfied.

Let $n$ be an integer $\geq 2$. Assume that for any minimal singularity, any test curve with inner rate $n - 1$ satisfies Conditions (\ua{1.1}) and (\ua{2}). Let $\gamma$ be the $\rho$-image of a curvette with inner rate $q_\gamma = n$. We use again the notations $\ell$, $e$, $\ell'$ and $e'$ introduced for Proposition 6.1 and we set $C = e^{-1}(0)$.

Consider the point $q = \gamma^* \cap C$, where * means strict transform by $e$. Since $n \geq 2$, the strict transform $\Delta^*$ contains $q$. Since $\ell$ is generic for its polar curve and since $e'$ is the blow-up of the origin, then the fiber $\ell'^{-1}(q)$ contains a unique point $p$ which belongs to the strict transform $\Pi^*$ of $\Pi$ by $e'$.

Claim 1. $\gamma$ satisfies condition (\ua{1.1}).

Proof. Let $\sigma$ be a component of $\ell^{-1}(\gamma)$. We have to prove that $(\sigma, 0)$ is smooth.

Assume first that the strict transform $\sigma^*$ of $\sigma$ by $e'$ meets $E' = e'^{-1}(0)$ at a point $p' \in \ell'^{-1}(q)$ distinct from $p$. Then $p'$ does not belong to the strict transform $\Pi^*$ of $\Pi$ by $e'$. Therefore $(X', p')$ is smooth, $p'$ is a smooth point of $E' = e'^{-1}(0)$ by (i) of Proposition 6.1 and the map germ $\ell': (X', p') \to (U', q)$ is an isomorphism by (ii) of Proposition 6.1. Since $\gamma^*$ is a smooth curve transverse to $C$ at $q$, then $(\ell'^{-1}(\gamma^*), p') = (\sigma^*, p')$ is a curvette of $E'$. Since $(X, 0)$ is minimal, the multiplicity of a generic linear form on $(X, 0)$ has multiplicity 1 along $E'$. By [11, 1.1], this implies that $\sigma$ is a smooth curve of $(X, 0)$.

Assume now that $\sigma^* \cap E = p$. According to Proposition 6.1 the map germ $\ell': (X', p) \to (U', q)$ is a generic projection of $(X', p)$. Moreover, its discriminant and polar curves are respectively the strict transform $(\Delta^*, q)$ of $(\Delta, 0)$ by $e$ and the strict transform $(\Pi^*, p)$ of $(\Pi, 0)$ by $e'$. Since $\gamma$ has rate $n \geq 2$, then its strict
transform \((\gamma^*, q)\) by the blow-up of 0 is a test curve with inner rate \(n - 1\) (Remark 4.2). Taking \((\gamma^*, q)\) as test curve for \((X', p)\), we apply the induction assumption: \((\gamma^*, q)\) satisfies Condition \((*)\), i.e., \((\gamma^*, q)\) is a smooth curve on \((X', p')\). Let \(\pi_0: (X_0, E) \to (X, 0)\) be the minimal resolution of \((X, 0)\). It factors through \(e'\). Let \(\pi': X_0 \to X'\) be the resolution of \(X'\) such that \(\pi_0 = e' \circ \pi'\). Since \(\sigma^*\) is a smooth curve on \((X', p')\), then by [11, 1.1], its strict transform \(\sigma''\) by \(\pi'\) is a curve at a smooth point of \(\pi'^{-1}(p')\) (along which the multiplicity of the maximal cycle is 1).

The curve \(\sigma''\) is also the strict transform of \(\sigma\) by \(\pi_0\), and since the maximal cycle of \((X, 0)\) is reduced, then again by [11, 1.1] (we use here the converse statement) then \((\sigma, 0)\) is a smooth curve on \((X, 0)\).

**Claim 2.** \(\gamma\) satisfies Condition \((*)\).

*Proof.* Let us write \(\ell^{-1}(\gamma)\) as the union \(\ell^{-1}(\gamma) = \eta_1 \cup \eta_2\) where \(\eta_2\) is the union of components of \(\ell^{-1}(\gamma)\) whose strict transforms by \(e'\) contain \(p\).

Let \(\sigma\) be a component of \(\eta_1\) and let \(p' = \sigma^* \cap E'\). The strict transform by \(e'\) of another component \(\sigma_1\) of \(\ell^{-1}(\gamma)\) meets \(E'\) at a point in \(\ell^{-1}(q)\) different from \(p'\). Therefore \(\sigma\) and \(\sigma_1\) have distinct tangent lines so their contact exponent equals 1. This proves that any component of \(\eta_1\) has contact exponent 1 with any other component of \(\ell^{-1}(\gamma)\).

It remains to prove Condition \((*)\) for two components \(\delta_1\) and \(\delta_2\) of \(\eta_2\). Let \(\eta_0\) the rate associated to \(\delta_1\) and \(\delta_2\) as in Condition \((*)\). The strict transforms \(\delta_1^*\) and \(\delta_2^*\) of \(\delta_1\) and \(\delta_2\) by \(e'\) are two components of the liftings \(\ell^{-1}(\gamma^*)\) of the test curve \((\gamma^*, q)\) for the surface germ \((X', p')\), and the rate associated to \(\delta_1^*\) and \(\delta_2^*\) as in Condition \((*)\) for \((X', p')\) equals \(q_0 - 1\). We now use the induction assumption: since \(\gamma^*\) satisfies Condition \((*)\) as a test curve of \((X', p')\) with rate \(n - 1\), then \(q_0 - 1 = n - 1\), so \(q_0 = n\). This proves Claim 2.

**Case 2.** We now assume \(\gamma\) is a curvette of \(\rho^{-1}(0)\) with inner rate \(q_0 = n + 1/2\) where \(n\) is an integer \(\geq 1\). Then, in suitable coordinates \(x\) and \(y\), \(\gamma\) is a curve with a Puiseux expansion of the form \(y = ax^{n+\frac{1}{2}}\) and there is a unique component \(\Delta'\) of \(\Delta\) with same type \(y = a'x^{n+\frac{1}{2}}\) higher order. Let \(q = \gamma^* \cap C = \Delta^* \cap C\) as in Case 1, and let \(\Pi' \subset \Pi\) such that \(\ell(\Pi') = \Delta'\) and \(p = \ell^{-1}(q) \cap \Pi^*\).

We will proceed again by induction on \(n\), using similar arguments as in Case 1. Assume first \(n = 1\), i.e., \(q_0 = 3/2\). Then \(\Delta'\) and \(\gamma\) are 3/2-cusps, i.e., equisingular to \(n^2 - n^3 = 0\), with contact exponent 3/2. The strict transforms \(\Delta^*\) and \(\gamma^*\) by \(e\) are smooth curves meeting \(e^{-1}(0)\) at the same point \(q\).

Let \(p' \in \ell^{-1}(q)\) be distinct from \(p\). Then the map germ \(\ell': (X', p') \to (U', q)\) is an isomorphism, so the germ \((\ell'^{-1}(\gamma^*), p')\) is a smooth curve tangent to \(E'\). Therefore, there is a unique component \(\sigma\) of \(\ell^{-1}(\gamma)\) whose strict transform by \(e'\) contains \(p'\), and it has multiplicity 2. So \(\sigma\) is a plane curve, and since it is smooth after one blow-up, it is a 3/2-cusp. Moreover, a similar argument as in the proof of Claim 1 shows that \(\sigma\) has contact exponent 1 with any other component of \(\ell^{-1}(\gamma)\).

Let us now deal with \((\ell'^{-1}(\gamma^*), p)\). According to Theorem 5.4, \(p\) is a smooth point of an exceptional curve obtained by blowing-up the intersection point between two exceptional curves of \(\ell'^{-1}(C)\) corresponding to a central edge in the resolution graph, and \((\ell'^{-1}(\gamma^*), p)\) consists of the strict transform of a component of \(\ell^{-1}(\gamma)\) which is equisingular to \(\Pi^*\). So this component is a cusp, i.e., its unique rate is 3/2. This implies that \(\gamma\) satisfies Conditions \((*)\) and \((*)\).

The rest of the induction uses the same arguments as in Case 1. This completes the proof of the “if” direction of Theorem 1.2.
7. Explicit example of lifting of test curves

The aim of this section is to give in an explicit example a flavor of Conditions 
\(\ast 1\) and \(\ast 2\) of Theorem 4.5 in the case of a minimal singularity. We return back
 to Example 5.7 and we give for some examples of test curves \((\gamma, 0)\), the resolution
 graph of the lifting \(\ell^{-1}(\gamma)\) on the left and the resolution of its generic projection
 \(\ell'(\ell^{-1}(\gamma))\) on the right. Figure 3 is for the test curve given by a generic line. Figures
 4 and 5 are for two test curves which are \(\rho\)-images of curvettes of the exceptional
curves corresponding respectively to the vertices \(v_1\) and \(v_2\).

Figure 3.

Figure 4.

8. Rational and Lipschitz normally embedded implies minimal

In this section, we prove the other direction of Theorem 1.2: any rational surface
 singularity which is Lipschitz normally embedded is minimal

Remark 8.1. A Lipschitz normally embedded surface singularity is not necessarily
minimal. A counter-example is given by the (non rational) hypersurface in \(\mathbb{C}^3\) with
 equation \(xy(x + y) + z^4 = 0\). It is a superisolated singularity. The graph of
its minimal resolution factorizing through Nash has four vertices. It consists of
a central vertex and three bamboos of length one, these three leaves being the
\(L\)-nodes, and the central vertex the single \(P\)-node.
Proof. Let $(\tilde{X}, E)$ be the minimal resolution of $(X, 0)$, $Z$ the minimal cycle and $E = \bigcup E_i$. The multiplicity of $Z$ at any $\mathcal{L}$-curve is 1, since $(X, 0)$ is Lipschitz normally embedded. Consider Laufer’s algorithm for finding $Z$ ([13, Proposition 4.1]), and let $E_j \subset E$ be the last curve one adds in the algorithm before one obtains $Z$. Assume that $E_j$ is not an $\mathcal{L}$-curve, so $Z \cdot E_j = 0$. Let $Z'$ be the penultimate cycle obtained by Laufer’s algorithm. Then $Z' = Z - E_j$ and $Z' \cdot E_j = -E_j^2 > 1$ which contradicts $(X, 0)$ being rational by Laufer’s criterion ([13, Theorem 4.2]). So the last curve added by Laufer’s algorithm is always an $\mathcal{L}$-curve.

One can always run Laufer’s algorithm such that each curve is added once, before any curve is added a second time. So unless $Z = \sum E_i$ there would be an $\mathcal{L}$-curve with multiplicity $> 1$, which is a contradiction. Thus $(X, 0)$ is minimal. □
